*A new kid on the block: The stratification pattern for space-filling,  
with dimension by weight tables  
which is available at  
<https://doi.org/10.1002/qre.3627>*

How does **design performance on various space-filling metrics**  
affect **prediction performance of the emulator model**  
*in practice?*

## Curse of dimensionality

16 points in 1D

16 points in 2D

## Computer experiments for quantitative variables:

- replication not needed (same input  $\rightarrow$  same output)
- easy to modify levels  $\rightarrow$  columns can have many levels
- large experimental space may need non-linear model, possibly non-parametric

**Latin hypercube design (LHD)** in  $n$  runs: each column has levels 0 to  $n - 1$

## Orthogonal array (OA)

## Optimized LHD

## Less optimized LHD

## Completely aliased LHD

Introduction

Stratification  
pattern with  
refinement

Further metrics for  
space-filling

Simulation  
exercise

Conclusions

References

### Orthogonal array (OA)

### Optimized LHD

LHD = expansion of OA (non-unique operation)

OA = collapsed version of LHD (unique operation)

Any expansion of the OA has a single point in each of the sixteen cells.

For applicability of stratification pattern:

- each column has  $s^\ell$  levels for some  $s$  and  $\ell$  (e.g.  $2^2$  or  $2^4$ ),
- individual columns can be coarsened to  $s^1, \dots, s^{\ell-1}$  levels,
- one can consider
  - $s$  to  $s^\ell$  strata for individual columns (1D), e.g. 2, 4, 8, 16,
  - $s^2$  to  $s^{2\ell}$  strata for pairs of columns (2D), e.g., 4, 8, 16, 32, 64, 128, 256,
  - ...  $s^d$  to  $s^{d\ell}$  strata for sets of  $d < m$  columns ( $dD$ )
  - $s^m$  to  $s^{m\ell}$  strata involving all  $m$  columns ( $mD$ )
- Coarser stratifications and lower dimensions are considered more important.

Stratification pattern for given  $s$  and  $\ell$ :

$$(S_1, S_2, \dots, S_{m\ell})$$

$S_j$  measures imbalance from stratification into  $s^j$  strata

Perfect balance  $\rightarrow S_j = 0$ .

Consider, e.g.,  $16 = 2^4$  strata for the four example designs ( $s = 2, j = 4$ ):

- 1D is perfectly balanced for all LHDs (and impossible for OA)
- 2D:  $4 \times 4$  or  $8 \times 2$  or  $2 \times 8$  for all LHDs,  $4 \times 4$  only for the OA

Conclusions

References

- **minimum distance** between pairs of points should be **maximal (maximin)**, the larger the better (Johnson, Moore and Ylvisaker 1990)
- $\phi_p$ : minimizing  $\phi_p$  serves as a norm-based emulation of maximin, the smaller the better (Morris and Mitchell 1995)

$$\phi_p(\mathbf{x}) = \left( \sum_{\{i,j\} \subset \{1,\dots,n\}, i \neq j} d(\mathbf{x}^{(i)}, \mathbf{x}^{(j)})^{-p} \right)^{1/p}$$

## Centered $L_2$ discrepancy (Hickernell 1998):

measures discrepancy from continuous uniform distribution on  $m$ -dimensional experimental hypercube, in our example case on  $[0, 15]^2$ .

With  $z_{ij}$  referring to a design rescaled to  $[0, 1]^m$ , centered  $L_2$  discrepancy is:

$$CD(\mathbf{x}) = \left(\frac{13}{12}\right)^m - \frac{2}{n} \sum_{i=1}^n \sum_{j=1}^m (1 + 0.5|z_{ij} - 0.5| - 0.5|z_{ij} - 0.5|^2) + \\ + \frac{1}{n^2} \sum_{i=1}^n \sum_{k=1}^n \prod_{j=1}^m (1 + 0.5|z_{ij} - 0.5| + 0.5|z_{kj} - 0.5| - 0.5|z_{ij} - z_{kj}|),$$

For a design  $\mathbf{X}$  with  $m$  columns, the maximum projection criterion (Joseph, Gul and Ba 2015) considers **2D projections** and requires minimizing

$$\psi(\mathbf{X}) = \left( \frac{1}{\binom{n}{2}} \sum_{i=1}^{n-1} \sum_{j=i+1}^n \frac{1}{\prod_{k=1}^m (x_{ik} - x_{jk})^2} \right)^{1/m} .$$

This criterion (Sun, Wang and Xu 2019) considers the average centered  $L_2$  discrepancy over all pairs of columns, i.e., over all 2D projections.

For the four above designs, it coincides with the centered  $L_2$  discrepancy, because there is only one pair.

Design columns should be as uncorrelated as possible.

- **maximum absolute correlation** between columns (the smaller the better) or
- average absolute correlation or
- average squared correlation
- ...

or further demands, regarding correlation also with product columns (Ye 1998 design)

Six 64 run designs were tested:

- two LHDs from the 1998 Ye construction (one optimized for maximum distance), which have uncorrelated columns and even correlation zero between linear and bilinear columns
- two SOAs (“**S**trong” or “**S**tratif**i**ed” **O**rt**h**ogonal **A**rrays) with eight-level columns that perform well on the stratification pattern
- expansions of the SOAs to LHDs, also called **G**eneral SOAs (GSOAs)

GSOA\_ST is best for all criteria except maximum absolute correlation (but still acceptable).

Ye designs have optimal correlation properties, including further ones not captured in any of the metrics.

Borehole function (deterministic, 8 meaningful inputs on very different scales, 9th irrelevant input)

For emulator model:

log water flow modeled via kriging using function `km` from R package

DiceKriging:

- optimizer BFGS
- up to 200 iterations with a nugget of  $10^{-8}$
- two alternative strategies of handling the huge differences between parameter ranges:
  - working on original scale with `km`'s `parscale` argument
  - working on  $[0, 1]^m$ , adjusting the inputs in the borehole function
- Gauss or Matern covariance structure

For each design under each of the four settings:

100 emulator models based on random allocations of variables to the design.

GSOA\_ST is best in terms of the metrics,  
but outperformed by the Ye designs [0,1] coding

The good performance of the Ye designs is not sufficiently explained by the metrics considered - is the strong correlation performance key?

Such questions deserve more attention, with a view to guiding practitioners.

Difficulties: Prediction performance strongly depends on

- the benchmarking problem considered
- the modelling strategy (even relative performance within the same benchmarking problem)

It is not trivial to design meaningful comparison settings.

But it should be done!
